#### ABSTRACT

A series system is simulated to obtain lower confidence limits on system reliability using Bayesian techniques. A comparison between classical and Bayesian methods is made. Random beta variate generators are developed and used in the simulation. The results of the simulation are tabulated for easy comparison of the Bayesian and classical methods. The values of lower confidence limits that are realized using the Bayesian method decrease as the number of components increase. In most cases, as the number of components increase, the Bayesian method appears to yield lower values of lower confidence limits than the classical method.

## I. INTRODUCTION

In a series system the reliability of the system, RS, depends upon the reliability of each of the k components or subsystems of which it is composed. This can be modeled as follows:

$$RS = \frac{k}{\pi} R_{i},$$

where R<sub>i</sub> is the reliability of the ith component. Using success/fail test data classical or Bayesian methods can be used to compute lower confidence limits on RS. In a simple system with few components the Bayesian method offers many advantages over the more conservative classical method. However, as the system becomes more complex with a higher number of components, problems start to arise with the use of standard Bayesian techniques.

The purpose of this paper is to compare classical and Bayesian methods of computing lower confidence limits. Computer simulations were used to determine lower confidence limits on system reliability using Bayesian methods. A Poisson approximation was used to obtain lower confidence limits for the classical approach. Several factors were varied but the main interest of the investigation was the effect of the number of components of a system on the values of lower confidence limits on system reliability.

### II. METHODS

In order to compute lower confidence limits on system reliability of a series system two methods can be used.

The first method to be discussed is the classical approach which is based solely on test results. The second method is the Bayesian approach which utilizes assumptions based on prior knowledge of similar systems.

### A. CLASSICAL METHOD

The classical approach to system reliability uses only the mission test data on each component. These results are then combined in order to obtain an estimate of the system reliability. In the most simple case where k components are each tested n times and there are no failures in any of the components it is assumed that this is equivalent to testing the entire system n times with no failures. In this case the lower  $100(1-\alpha)$ % confidence limit can be found in the same manner as with just one item. This is done by solving for p in the equation:

$$\sum_{j=s}^{n} {n \choose j} p^{j} (1-p)^{n-j} = \alpha$$

where s = number of successes.

The solution is a lower  $100(1-\alpha)$ % confidence limit on RS.

In the case of zero failures  $RS_{L(\alpha)} = \sqrt[N]{\alpha}$ . When only one failure occurs the same procedure can be used. However,

when more than one failure occurs the procedure becomes more complicated.

In the case where each component is tested n times and there are few component failures, an approximation to the classical value of  ${\rm RS}_{{\rm L}(\alpha)}$  can be found as follows.

Let 
$$Q_i = 1 - R_i$$
,

then RS = 
$$\sum_{i=1}^{k} (1-Q_i)$$
.

If the Q;'s are small then

RS = 1 - 
$$\sum_{i=1}^{k} Q_i$$
.

Let  $f_i$  = the number of failures on the ith component. Since  $f_i$  is a sum of n Bernoulli trials it is binomial  $(n,Q_i)$ . If  $Q_i$  is small then each  $f_i$  is approximately Poisson  $(nQ_i)$ .

Let 
$$F = \sum_{i=1}^{k} f_i$$
;

then F is approximately Poisson  $(n \sum_{i=1}^{k} Q_i)$ ,

and the upper  $100(1-\alpha)$ % confidence limit [Ref. 1] for

$$\sum_{i=1}^{k} Q_i$$
 is  $\frac{\chi_{\alpha}^2$ ,  $2(F+1)}{2n}$ , where  $\chi_{\alpha}^2$ ,  $2(F+L)$  is the  $100(1-\alpha)$ th

percentile of the  $\chi^2$  distribution with 2(F+1) degrees of freedom.

Thus 
$$RS_{L(\alpha)} = 1 - \frac{\chi_{\alpha}^2, 2(F+1)}{2n}$$

is an approximation to the classical value for a lower  $100(1-\alpha)$ % confidence limit on RS.

#### B. BAYESIAN METHOD

The Bayesian approach to system reliability is to treat each component reliability, R<sub>i</sub>, as a random variable. One particular method is to assume that each component reliability has a beta distribution. The beta density function can be defined as follows:

$$F(r;a,b) = \frac{1}{B(a,b)} r^{a-1} (1-r)^{b-1}$$
 for  $0 \le r \le 1$ ,  $a > 0$ ,  $b > 0$ ,

where 
$$B(a,b) = \frac{\Gamma(a) \Gamma(b)}{\Gamma(a+b)}$$
.

A prior beta density B(r;a,b) is assumed for each component before testing begins. The test data is then used to obtain a posterior beta density B(r;a+s,b+f) where s is the number of successful tests and f is the number of failures for the component.

By generating a random beta variate for each component based on its posterior density a value of RS is calculated using the model:

$$RS = \sum_{i=1}^{k} R_{i}.$$

A distribution of RS values is simulated by repeating this procedure. The lower confidence limits are thus estimated

by the appropriate percentile points of the simulated distributions of RS values.

The main advantage of the Bayesian method is that past experience with technically similar hardware can be used to determine appropriate priors for each component. This allows higher reliability goals to be met with less testing. However, some precautions must be observed in selecting the beta priors. Choosing a beta prior of B(r;a,b), where a and b are integers, is equivalent in the classical sense to assuming that (a+b-1) tests have been performed and that a of these were successes. It is equivalent because the  $\alpha$ th percentile point of the B(r;a,b) distribution is the lower  $100(1-\alpha)$ % confidence limit for p when there are (a+b-1). Bernoulli trials, each with probability p of success, and a of these trials are successful. This is readily apparent from an identity that relates the beta distribution to the binomial distribution [Ref. 2].

As the sum of the beta parameters (a+b) in the prior density increases relative to the number of tests to be observed the resulting lower confidence limits are more of a function of the assumed prior density than of the test results. One procedure is to limit the sum of the two parameters to a function of the number of tests. If the b parameter is less than one a different problem exists even though the sum of the parameters is small. This problem can be shown by the following discussion.

For any  $\alpha$ , a family of beta distributions exist such that the ath percentile point of each is the same. If the b parameter is set equal to 1, then for any B(r;a,b) distribution an a\* can be found such that the ath percentile point of B(r;a,b) and B(r;a\*,1) are the same. The B(r;a\*,1) distribution is convenient since it can be related to the classical case of having already tested a\* items with no failures. The problem when the b parameter is less than one can be shown by converting the initial B(r;a,b) prior to a B(r; a\*, 1) prior. In this case if there are no failures the posterior distribution will be B(r;a\*+s,1) where s is the number of successful tests. If the initial beta prior is not converted the posterior distribution will be B(r;a+s,b), which can be converted to B(r;(a+s)\*,1). all cases that were investigated the (a+s)\* was larger than a\*+s when the b parameter was less than one. Thus, in an equivalent classical sense, it appears that each successful test will be counted as more than one success. amplification effect seems to increase rapidly as the b parameter approaches zero. Also if the beta prior (B(r;a,b), where b is less than one, is converted to a beta B(r;a\*,1) to ensure that each success counts only as one success, the resulting a\* may be too large. The details of the conversion are given in the next section and a table of the resulting a\*'s for various values of b can be found in Appendix A.

# III. SIMULATION

The purpose of this investigation was to compare lower confidence limits derived by using Bayesian methods with those obtained by using the classical method. In order to simplify the simulation and to be able to make comparisons it was assumed that each of the components had the same beta prior density and that each component was mission tested the same number of times. Using the same beta prior for each component is not a necessary condition for the simulation to work.

#### A. SIMULATION PROCEDURE

A series system of k components was simulated in the following manner. Let  $\mathrm{Bl}_{\mathbf{i}}(r;a_{\mathbf{i}},b_{\mathbf{i}})$  be the initial beta prior for  $\mathrm{R}_{\mathbf{i}}$ . For this investigation the following three beta priors were used:  $\mathrm{B}(r;5.0,0.03)$ ,  $\mathrm{B}(r;5.0,0.05)$  and  $\mathrm{B}(r;5.0,0.10)$ . For each  $\mathrm{Bl}_{\mathbf{i}}(r;a_{\mathbf{i}},b_{\mathbf{i}})$  a new beta prior,  $\mathrm{B2}_{\mathbf{i}}(r;a_{\mathbf{i}}^*,1)$ , was computed such that the 10th percentile point of  $\mathrm{B2}_{\mathbf{i}}(r;a_{\mathbf{i}}^*,1)$  was the same as the 10th percentile point of  $\mathrm{B1}_{\mathbf{i}}(r;a_{\mathbf{i}},b_{\mathbf{i}})$ . The value for  $a_{\mathbf{i}}^*$  is easily computed since if the b parameter is 1 then the percentile point (P) of a  $\mathrm{B}(x;a,1)$  distribution is given by the equation  $\mathrm{P}=x^a$ . Thus  $a_{\mathbf{i}}^*=\ln(0.10)/\ln x$ , where x is the 10th percentile point of  $\mathrm{B1}_{\mathbf{i}}(r;a_{\mathbf{i}},b_{\mathbf{i}})$ .

Let  $n_i$  = the number of trials for each component, and  $s_i$  = the number of successes for each component.

The B2 $_{i}$ (r; $a_{i}^{*}$ ,1) prior was then adjusted in the following manner:

A beta posterior  $B3_i(r;a_i,b_i)$  for each  $R_i$  was computed in four cases as follows:

Case 1 
$$B3_{i}(r; a_{i}, b_{i}) = B1_{i}(r; a_{i} + s_{i}, b_{i} + n_{i} - s_{i})$$
  
Case 2  $B3_{i}(r; a_{i}, b_{i}) = B21_{i}(r; a_{i} + s_{i}, 1 + n_{i} - s_{i})$   
Case 3  $B3_{i}(r; a_{i}, b_{i}) = B22_{i}(r; a_{i} + s_{i}, 1 + n_{i} - s_{i})$   
Case 4  $B3_{i}(r; a_{i}, b_{i}) = B23_{i}(r; a_{i} + s_{i}, 1 + n_{i} - s_{i})$ 

By generating  $B3_i(r;a_i,b_i)$  random variates, which represent the posterior distributions of each of the components, a value for RS was obtained by taking their product. This procedure was repeated 500 times and realized values for RS were then ordered. The lower  $100(1-\alpha)$ % confidence limits were then determined by selecting the appropriate percentile points of the simulated distribution on RS.

#### B. GENERATION OF RANDOM BETA VARIATES

Two means of generating random beta variates were used in the simulation. In the case where the b parameter of the B(r;a,b) distribution was an integer an exponential generator was used to realize random beta variates. In the case

of noninteger parameters, Monte Carlo rejection techniques were used.

In order to generate random B(r;a,b) variates where b is an integer the following logic was used [Ref. 3]. Assume Y is B(y;a,b).

Define U = -lnY.

Then the moment generating function

$$M_{U} t = E[e^{tU}] = E[e^{-1nY}] = E[Y^{-t}]$$
.

Thus

$$E[Y^{-t}] = \frac{1}{B(a,b)} \int_{0}^{1} y^{a-t-1} (1-y)^{b-1} dy ,$$

$$= \frac{B(a-t,b)}{B(a,b)} = \frac{\Gamma(a+b)}{\Gamma(a) \cdot \Gamma(b)} \cdot \frac{\Gamma(b)\Gamma(a-t)}{\Gamma(a+b-t)} ,$$

$$= \frac{a(a+1) \dots (a+b-1)}{(a-t)(a+1-t) \dots (a+b-1-t)}$$

$$= \frac{a+b-1}{j=a} (\frac{1}{1-t}) .$$

Since 
$$(\frac{1}{1-t})$$

is the moment generating function for an exponential random variable with parameter  $\lambda$ , then U is the sum of b independent exponential random variables with failure rates a, a+1, ..., a+b-1,

i.e., 
$$U = \sum_{j=0}^{b-1} U_j$$
 where  $U_j$  is exp  $(a+j)$ .

Since  $Y = e^{-U}$ , random beta variates can be generated with the use of existing exponential generators. For the simulation, where the posterior distributions on  $R_i$  were  $B3_i(r;a_i,b_i)$  and the  $b_i$ 's were integers, values for RS were obtained by using the following formula:

$$-1nRS = \sum_{i=1}^{k} \sum_{j=0}^{b_i-1} U_{ij},$$

where

$$U_{ij}$$
 is exponential  $(a_i+j)$ .

In the case where the b parameter of the beta density was noninteger, random beta variates were generated by using Monte Carlo rejection techniques [Ref. 4]. Since this investigation was concerned with small values of the b parameter the Monte Carlo technique had to be modified slightly. The procedure that was used is outlined below.

1. Compute P  $P=Prob(X \le 0.999)$  where X is B(x;a,b).

2. Set H H=Max value of  $f_{\chi}(x)$  for  $0 \le x \le 0.999$ .

3. Generate R R=Random U(0,1) number.

4. If R > P Then  $X_{i} = 1.0$ , Go to 3.

5. Generate R1 R1=Random U(0,1) number.

6. If R1 > 0.999 Then Go to 5.

7. Generate R2 R2=Random U(0,1) number.

8. If  $(R2 \cdot H \leq f_X(R1))$  Then  $X_i = R1$ , Go to 3.

9. Go to 5.

This procedure was repeated until 500 random beta variates were realized for each posterior density.

#### C. MODIFICATION OF SUBROUTINE BDTR

Subroutine BDTR [Ref. 5] was used in the simulation to convert beta priors and to compute beta densities in the generation of random beta variates using Monte Carlo techniques. The subroutine BDTR computes the probability that the random variable U is less than or equal to x, where U is distributed according to the beta (u;a,b) distribution and 0 < x < 1. The value of the density at x is also computed. In order for the computations to be valid the sum of the parameters must be greater than or equal to one. In the subroutine BDTR this condition is met by restricting both parameters to values greater than or equal to 0.5. The subroutine was modified so that smaller values of the b parameter could be used since the a parameter was always greater than or equal to one. Two additional variables were added to the parameter list of the subroutine which increased the efficiency of the simulation by acting as flags and saving values when the subroutine was being called during the generation of random beta variates. All modifications to the subroutine are shown in the listing of the computer program.

### IV. RESULTS

The results of the simulation are given in tables for each of the three beta priors that were used. The number of failures was the total number of failures in all of the components. For n=50, and in a similar manner where n=75 and n=100, the failures were assigned as follows:

| Failures | Suc            | Successes                               |                   |                            |  |  |  |  |  |
|----------|----------------|---|-------------------|----------------------------|--|--|--|--|--|
| 0        | si             | =                                       | 50,               | i=1,2,,k                   |  |  |  |  |  |
| 1        | s <sub>i</sub> | =                                       | 49,<br>50,        | i=1<br>i=2,3,,k            |  |  |  |  |  |
| 2        | <sup>s</sup> i | ======================================= | 49,<br>50,        | i=1,2<br>i=3,4,,k          |  |  |  |  |  |
| 3        | s <sub>i</sub> |   |                   | i=1<br>i=2<br>i=3,4,,k     |  |  |  |  |  |
| 4        | s <sub>i</sub> | ======================================= | 48,<br>50,        | i=1,2<br>i=3,4,,k          |  |  |  |  |  |
| 5        | s <sub>i</sub> |   | 48,<br>49,<br>50, | i=1,2<br>i=3<br>i=4,5,,k   |  |  |  |  |  |
| 6        | <sup>s</sup> i |   | 48,<br>49,<br>50, | i=1,2<br>i=3,4<br>i=5,6,,k |  |  |  |  |  |

The beta priors for the Bayesian cases were as follows:

Case 1 B1(r;a,b)

Case 2 B21(r;a,1) 
$$a = min(0.75n,a^*)$$
  $n=50,75,100$ 

Case 3 B22(r;a,1)  $a = min(1.0 n,a^*)$   $n=50,75,100$ 

Case 4 B23(r;a,1)  $a = min(1.5 n,a^*)$   $n=50,75,100$ 

The appropriate values for B1(r;a,b) and B2(r;a\*,1) are given at the top of each table.

B1(r;5.0,0.03) converts to B2(r;596.8,1)

Fifty tests for each component

### V. CONCLUSIONS

The results of the simulation indicate that the classical approach to system reliability usually yields higher values of lower confidence limits than the Bayesian approach. When there are 10 or more components, only the beta priors with b parameters less than one provided higher values of lower confidence limits than the classical approach. When using the Bayesian approach, the effect of each prior density assumption is to obtain a more optimistic posterior density on each component reliability. However, there is some probability mass that is still assigned to small values of each R<sub>i</sub>. Thus, as the number of components increase the probability of small values of RS increases since RS is a product of the R<sub>i</sub>'s. Therefore, as the number of components increase, the effect of the prior density assumptions tends to diminish.

# APPENDIX A

## BETA DENSITY CONVERSIONS

The following table lists values of  $a^*$ , where  $a^*$  is such that the 10th percentile point of a B(x;a,b) distribution is the same as the 10th percentile point of a  $B(x;a^*,1)$  distribution.

A series system is simulated to obtain lower confidence limits on system reliability using Bayesian techniques. A comparison between classical and Bayesian methods is made. Random beta variate generators are developed and used in the simulation. The results of the simulation are tabulated for easy comparison of the Bayesian and classical methods. The values of lower confidence limits that are realized using the Bayesian method decrease as the number of components increase. In most cases, as the number of components increase, the Bayesian method appears to yield lower values of lower confidence limits than the classical method.
